**ABSTRACT**

The HIFI instrument on board the Herschel Space Observatory has been used to observe interstellar nitrogen hydrides along the sight-line towards G10.6–0.4 in order to improve our understanding of the interstellar chemistry of nitrogen. We report observations of absorption in NH, NH2, and NH3 towards G10.6–0.4 in all possible inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion transitions. Interstellar NH2 was first observed by van Dishoeck et al. (1993) in absorption towards Sgr B2 in three fine-structure components of the para-NH2 J = 1 ← 0 transition with partially resolved hyperfine structure at frequencies 461 to 469 GHz. Further absorption lines of both ortho and para forms of NH2 and NH were observed through use of the long-wavelength spectrometer aboard ISO (Cernicharo et al. 2000; Goicoechea et al. 2004; Polehampton et al. 2007). The ISO observations were unable to resolve the hyperfine structure of either molecule. Ammonia, NH3, was the first polyatomic molecule to be identified in interstellar space (Cheung et al. 1968) by means of its microwave inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006). With the unique capabilities of Herschel Space Observatory (Pilbratt et al. 2010) transitions between 157 and 625 μm (0.48–1.9 THz) are available with the Heterodyne Instrument for the Far-Infrared (HIFI; de Graauw et al. 2010) with very high sensitivity. This allows searches for spectrally resolved, spectroscopy. Subsequent observations by Crawford & Williams (1997) and Weselak et al. (2009) have yielded six lines of sight where column densities of both NH and H2 are directly measured. The average value of the column density ratio in these diffuse and translucent sightlines is N(NH)/N(H2) = 3 × 10−9. Interstellar NH2 was first observed by van Dishoeck et al. (1993) in absorption towards Sgr B2 in three fine-structure components of the para-NH2 J = 1 ← 0 transition with partially resolved hyperfine structure at frequencies 461 to 469 GHz. Further absorption lines of both ortho and para forms of NH2 and NH were observed through use of the long-wavelength spectrometer aboard ISO (Cernicharo et al. 2000; Goicoechea et al. 2004; Polehampton et al. 2007). The ISO measurements were unable to resolve the hyperfine structure of either molecule. Ammonia, NH3, was the first polyatomic molecule to be identified in interstellar space (Cheung et al. 1968) by means of its microwave inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006).

**1. Introduction**

Molecular hydrides are important in the chemistry of the interstellar medium since they often appear in the first steps in chains of reactions that lead to more complex species. The production pathways of nitrogen-bearing molecules are still rather uncertain since key species, such as NH, NH2, and NH3, have not been widely observed. Even the first identified polyatomic interstellar molecule, ammonia (NH3), has been widely observed mainly in its para symmetry form, which leaves its formation mechanism poorly constrained in the diffuse interstellar gas. Both gas-phase chemistry and grain surface reactions have been proposed as formation mechanisms, but clearly more observations are needed for a better understanding.

Both NH and NH2 are well known in comets (e.g. Swings et al. 1941; Meier et al. 1998; Feldman et al. 1993), and have been observed in stellar photospheres (e.g. Schmitt 1969; Farmer et al. 1941; Meier et al. 1998; Feldman et al. 1993), and have been observed in stellar photospheres (e.g. Schmitt 1969; Farmer & Norton 1989) via their electronic, vibration-rotation, and high rotational transitions. Interstellar NH was first detected in the interstellar medium by Meyer & Roth (1991) by optical absorption spectroscopy. Subsequent observations by Crawford & Williams (1997) and Weselak et al. (2009) have yielded six lines of sight where column densities of both NH and H2 are directly measured. The average value of the column density ratio in these diffuse and translucent sightlines is N(NH)/N(H2) = 3 × 10−9. Interstellar NH2 was first observed by van Dishoeck et al. (1993) in absorption towards Sgr B2 in three fine-structure components of the para-NH2 J = 1 ← 0 transition with partially resolved hyperfine structure at frequencies 461 to 469 GHz. Further absorption lines of both ortho and para forms of NH2 and NH were observed through use of the long-wavelength spectrometer aboard ISO (Cernicharo et al. 2000; Goicoechea et al. 2004; Polehampton et al. 2007). The ISO observations were unable to resolve the hyperfine structure of either molecule. Ammonia, NH3, was the first polyatomic molecule to be identified in interstellar space (Cheung et al. 1968) by means of its microwave inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006).

With the unique capabilities of Herschel Space Observatory (Pilbratt et al. 2010) transitions between 157 and 625 μm (0.48–1.9 THz) are available with the Heterodyne Instrument for the Far-Infrared (HIFI; de Graauw et al. 2010) with very high sensitivity. This allows searches for spectrally resolved, spectroscopy. Subsequent observations by Crawford & Williams (1997) and Weselak et al. (2009) have yielded six lines of sight where column densities of both NH and H2 are directly measured. The average value of the column density ratio in these diffuse and translucent sightlines is N(NH)/N(H2) = 3 × 10−9. Interstellar NH2 was first observed by van Dishoeck et al. (1993) in absorption towards Sgr B2 in three fine-structure components of the para-NH2 J = 1 ← 0 transition with partially resolved hyperfine structure at frequencies 461 to 469 GHz. Further absorption lines of both ortho and para forms of NH2 and NH were observed through use of the long-wavelength spectrometer aboard ISO (Cernicharo et al. 2000; Goicoechea et al. 2004; Polehampton et al. 2007). The ISO observations were unable to resolve the hyperfine structure of either molecule. Ammonia, NH3, was the first polyatomic molecule to be identified in interstellar space (Cheung et al. 1968) by means of its microwave inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006).

**2. Observations**

The HIFI instrument on board the Herschel Space Observatory has been used to observe interstellar nitrogen hydrides along the sight-line towards G10.6–0.4 in order to improve our understanding of the interstellar chemistry of nitrogen. We report observations of absorption in NH, NH2, and NH3 towards G10.6–0.4 in all possible inversion transitions. Although NH3 has been widely observed in dark clouds and star-forming regions, there have been very few measurements of the inversion lines in the diffuse interstellar gas (Nash 1990; Liszt et al. 2006). With the unique capabilities of Herschel Space Observatory (Pilbratt et al. 2010) transitions between 157 and 625 μm (0.48–1.9 THz) are available with the Heterodyne Instrument for the Far-Infrared (HIFI; de Graauw et al. 2010) with very high sensitivity. This allows searches for spectrally resolved,
The ultra-compact HII region G10.6−0.4 in the star-forming W31 complex is an extremely luminous submillimetre and infrared continuum source. The source is located within the so-called 30 km s$^{-1}$ arm at a kinematic distance of 4.8 kpc (Fish et al. 2003). The gas associated directly with G10.6−0.4 is detected in the velocity range $V_{\text{LSR}} \approx -15$ to $+5$ km s$^{-1}$, while the foreground gas along the line of sight is detected at $V_{\text{LSR}} \approx 5$ to 55 km s$^{-1}$. The focus of this paper is on the diffuse interstellar gas traced by the absorption lines.

2. Observations

The observations, which took place in March 2010, are summarised in Table 1. The $2_0-1_0$ and $2_1-1_1$ NH$_3$ transitions were observed in the same band. We used the dual beam switch mode and the wide band spectrometer (WBS) with a bandwidth of 4 GHz and an effective spectral resolution of 1.1 MHz. The corresponding velocity resolution is about 0.3 km s$^{-1}$ at the higher frequencies and 0.6 km s$^{-1}$ at 572 GHz. In addition, simultaneous observations were performed using the high-resolution spectrometer (HRS) with an effective spectral resolution of 0.25 MHz ($\Delta \nu \sim 0.1$ km s$^{-1}$) and a bandwidth of 230 MHz. Three observations were carried out with different frequency settings of the local oscillator (LO) corresponding to a change of approximately 15 km s$^{-1}$ to determine the sideband origin of the lines. Two orthogonal polarisations were used during all observations.

The half-power beam width of the telescope is 37, 22, and 17$'$ at 572, 953, and 1215 GHz, respectively. Pointing was centered at RA = 18$^h$10$^m$28.70$^s$, Dec = -19$^\circ$55$'$50$''$ (J2000). The reference beams were located 3$'$ on either side of the source and the calibration is described by Roelfsema (2010).

We have used the standard Herschel pipeline to Level 2 which provides fully calibrated spectra. The data were first analysed using Herschel interactive processing environment (HIPE$^1$; Ott 2010) version 2.4, and in parallel we also used the software package xs$^2$. The data quality is excellent with very

1 HIPE is a joint development by the Herschel Science Ground Segment Consortium, consisting of ESA, the NASA Herschel Science Center, and the HIFI, PACS and SPIRE consortia.

low intensity ripples, two polarisations that are in agreement to better than 10%, and very good agreement between the three LO-tunings without contamination from the image sideband. We thus average the three LO-tunings and both polarisations in both spectra, except for NH$_3$ at 572 GHz and NH$^+$ which display ripples in the V- and H-polarisation, respectively, and were therefore not included. The resulting rms noise is 11, 120, 50, 51, and 74 mK for NH$_3$ at 572 and 1215 GHz, for NH, NH$_2$, and NH$^+$, respectively.

3. Results

Figure 1 shows the double sideband WBS spectra of all observed transitions. The frequency scale is converted as customary to Doppler velocities relative to the local standard of rest (V$_{LSR}$). All spectra, except NH$^+$ which is not detected, show emission at negative velocities and a deep absorption at −1 km s$^{-1}$ associated with G10.6−0.4 as measured by observations of OH masers. At higher velocities we see a number of absorption features which are also seen in atomic hydrogen (Fish et al. 2003), HCO$^+$, HNC, HCN and CN (Godard et al. 2010). The only transition which does not show absorption components from the foreground material is ortho-NH$_3$ 2$_0$−1$_0$.

The double-sideband calibrated antenna temperatures shown in Fig. 1 have to be divided by two in order to get the correct continuum levels, $T_A$(cont), which are 0.6, 2.6, 2.6, 3.0 and 3.4 K for NH$_3$ at 572 GHz, NH$_2$, NH, NH$^+$, and NH$_3$ at 1215 GHz, respectively. The sideband gain ratio has been shown to be close to unity in previous PRISMAS observations (Neufeld et al. 2010b; Gerin et al. 2010), although departures at the 10% level have been seen at some frequencies (Neufeld et al. 2010a). We here adopt a sideband ratio of unity.

Figure 2 shows a comparison of NH, NH$_2$, and para-NH$_3$ where the intensities are normalised to the continuum in a single sideband as $T_A$(cont)−1 assuming a sideband gain ratio of unity. The NH and NH$_2$ spectra are strikingly similar, despite their complicated hyperfine structures. The para-NH$_3$ spectra also show the same absorption pattern, although not as strongly. Figure 3 shows a similar comparison of ortho- and para-NH$_3$. Here, too, we see the same absorption pattern in both species, and strong emission and self-absorption in the ortho-line from the source itself. The strongest velocity components in the foreground material lie at $V_{LSR}$ = 16, 22.5, 27.5, 30 and 40.5 km s$^{-1}$.

The line opacities are calculated as $\tau = -\ln(T_{\text{line}}/T_A(\text{cont})-1)$. To be conservative and not include absorption from the source itself, we use the velocity interval 11−54 km s$^{-1}$. The total integrated opacities are $\int r\,dV = 20, 16, 9$, and 3.4 km s$^{-1}$ for NH, NH$_2$, NH$_3$ at 572 and 1215 GHz, respectively.

Even though unsaturated absorption lines provide straightforward determinations of opacity and column densities, the numerous hyperfine-structure components and velocity features complicate the analysis of both NH and NH$_2$. The spectroscopic properties of NH and NH$_2$ have been studied extensively and references, rest frequencies and molecular properties for NH and NH$_2$ are listed in the Cologne Database for Molecular Spectroscopy$^3$ (CDMS, Müller et al. 2005), and NH$_3$ in Jet Propulsion Laboratory$^4$ (JPL, Pickett et al. 1998).

In order to estimate the total column density from the integrated opacity, it is necessary to correct for the population of molecules in unobserved excited levels and to quantify any possible effect of stimulated emission. We have done this through non-equilibrium excitation calculations of integrated opacity with an enhanced version of the RADEX code$^5$ (van der Tak et al. 2007). Where collision rates are unknown, we have made guesses scaled in proportion to radiative line strengths. We assume diffuse molecular cloud conditions with $T_k = 30$ K and $n(H_2) = 500$ cm$^{-3}$. The background radiation is a model of the average Galactic background radiation in the solar neighbourhood plus the cosmic microwave background radiation. The excitation of the hydride molecules in diffuse gas is dominated by the background continuum radiation and not by collisions. The resulting excitation temperatures of the observed submillimetre transitions are typically 4−5 K, which are small enough compared to $h\nu/k$ that no correction for emission is required. All the optical depths of the hyperfine components that contribute to the line are summed. We have treated ortho- and para-forms of molecules together in the expectation that their relative abundances are fixed by the chemical formation process. Plausible rates of formation and destruction are included explicitly in the

The production of NH and NH$_2$ by purely gas-phase processes implies that NH is produced on grain surfaces (Mann & Williams 1984; Wagenblast et al. 1993; O’Neill et al. 2002). Such models, however, often predict up to 1000 times more NH than NH$_2$ (Hasegawa & Herbst 1993). An additional source of NH and NH$_2$ is fragmentation of ammonia by photodissociation in diffuse clouds. Models of ultraviolet illuminated photon-dominated regions predict NH$_2$/NH$_3$ < 1 and NH$_3$/NH < 1 in regions with extinction $A_V \leq 5$ mag (e.g. Sternberg & Dalgarno 1995). The abundance patterns that we see in diffuse molecular gas are clearly different from those in Sgr B2, where NH$_3$/NH$_2$/NH $\sim$ 100/10/1 and the fractional abundance of NH is a few times $\times 10^{-9}$ (Cernicharo et al. 2000; Goicoechea et al. 2004).

We have used two different approaches to chemical models in order to compare the nitrogen-hydride abundances with theory. First, we constructed a pseudo-time-dependent model with constant physical conditions including both gas-phase and surface chemistry (Hasegawa et al. 1992) with $A_V = 2$ and $3$, $n_H = 500$ and 5000 cm$^{-3}$, $T_{\text{gas}} = 30$ and 50 K, and $T_{\text{dust}} = 10$ K. The ultraviolet field is $1 G_0$, and the cosmic ray ionization rate is $\zeta = 1.3 \times 10^{-17}$ s$^{-1}$. The resulting abundances are found in Fig. A.1. Gas-phase chemistry alone does not match the observed abundances, failing by factors of 10 to 100 for NH and NH$_2$. Inclusion of processes on dust surfaces increases the abundances of the three neutral hydrides to $10^{-8}$-$10^{-9}$, but fails to match the high NH/NH$_3$ ratio. If the dominant source of NH$_3$ is association on surfaces and if the ortho/para ratio is fixed at a surface temperature below 20 K, then the 1215 GHz para line should be much weaker relative to the ortho 572 GHz line than is observed. The observed line ratio is perhaps somewhat better explained by a high formation temperature, which points to exoergic gas-phase formation of NH$_3$.

A second approach is to construct models of weak PDRs through use of the Meudon PDR code (Le Petit et al. 2006; Goicoechea & Le Bourlot 2007), which is a steady-state, depth-dependent model with pure gas-phase chemistry. We use parameters appropriate for diffuse clouds, UV = 0.5–5 $G_0$, $n_H = 100–1000$ cm$^{-3}$, $\zeta = 10^{-17}$–$10^{-15}$ s$^{-1}$, $A_V < 5$ and illuminate one side only. The results of the best fitting model are found in Fig. A.2. Although the resulting relative abundances of nitrogen-hydrides approach the observed ratios inside the cloud, the abundances relative to hydrogen are still too low.

### 5. Conclusions

Our first detections of spectrally resolved rotational transitions of nitrogen hydrides in the interstellar medium show remarkable similarities of line profiles and abundances towards our background source. The formation mechanisms are, however, difficult to explain. Neither standard gas-phase nor grain-surface chemistry can fully explain our observations, which may suggest that important reactions have been overlooked in the chemistry of interstellar nitrogen. Further analysis of the line profiles will yield abundance ratios in separate velocity components and will allow the nitrogen species to be compared directly with tracers of molecular hydrogen like CH and HF. Our sample will also be enlarged with seven additional sight-lines in the PRISMAS project. The chemical models will be refined and the possible role of turbulent dissipation regions will be assessed.
